March 6, 2017

In [1] the authors mention that there has been an increase in the volume of relational data generated today through a large number of sources. The large volume of data forces us to find solutions which can cope with them. Recently several hybrid approaches like HadoopDB, Hive, etc) have been introduced to handle this large data. Although these have been successful in handling large data, but their architecture makes them inefficient to handle suboptimal execution strategies. Therefore, in order to solve the above problem, Apache has developed Tajo, a relational, distributed data warehouse system on large clusters. It uses Hadoop Distributed File System (HDFS) for storing data and has its own query execution engine instead of the MapReduce framework.

This review document is provided for you to achieve your best. We have listed a number of obvious opportunities for improvement. When improving it, please keep this copy untouched and instead focus on improving report.tex. The review does not include all possible improvement suggestions and if you sea comment you may want to check if this comment applies elsewhere in the document.

Abstract: ')' used without opening '('. Don't use references. It is like a head start for a reader to get an idea about the paper. So citing is not important in this section.

Use latex bulletin or numbering instead of using merely numbers.

INTRODUCTION

In this Big Data era, Hadoop MapReduce [2][3], has been used for processing large-scale data sets. To handle a large amount of data, several hybrid approaches have been integrated with Hadoop and parallel databases. However, these cannot avoid the choice of suboptimal execution strategies because of their architecture, which led to the development of Tajo. Tajo [4] is a relational, distributed data warehouse system which runs on shared-nothing clusters. It uses Hadoop Distributed File System (HDFS) as the storage layer and has its own query execution engine instead of the MapReduce framework. A Tajo cluster consists of one master node and a number of workers. The master is responsible for the query planning and coordination among the workers.

The internals of Tajo has three main steps:-
1) Each worker has a local query engine that executes a directed acyclic graph (DAG) of physical operators. A DAG of operators can accommodate multiple sources of input and can be pipelined within the local query engine. Each worker generates query execution plan that can employ the existing query evaluation technique [5] [6] which lie in the database community.
2) Tajo can make use of various repartition methods specialized for specific queries. Consider joining two relations which are already sorted on the join key, Tajo needs to repartition only one relation to workers in which the corresponding part of another relation resides.
3) In Tajo, a physical plan that a worker executes is generated in runtime according to the available resources like memory, processing capability etc. of the workers. Workers can simultaneously execute different physical plans in the same phase which allows Tajo to maximize the utilization of the resources.

Don't use authors mention, just mention the fact and add the relevant reference.

ADVANTAGES OF TAJO OVER MAPREDUCE HIVE

In [1] the authors mention the limitations of Hadoop [3] [7] MapReduce-Hive technology due to its architecture led to the development of Tajo. These limitations are as follows:-

Single Source Input: The join operation in relational data

warehouses integrates heterogeneous data sets from multiple sources. But MapReduce supports only a single input source, the join operation is performed by dividing input relations through one map reduce job only which doesn't produce optimal results.

Fixed Data Flow: In [1] the authors mention the 3 phases of MapReduce which are the map, shuffle, and sort and reduce. The join operation and aggregation are performed in shuffle and sort phase. So it always follows a fixed execution flow leaving no room for any optimization needed in the processing. Sometimes processing huge datasets need to follow some hybrid map reduce flow which is not applicable to the Hadoop MapReduce framework.

Separate Storage: Some hybrid approaches [1] using the database layer require separate data storages for data distribution and processing. The partitioned data must be loaded into the database layer for performance benefits. In Hadoop, it takes a long time for data loads causing overhead other running workloads in the cluster because of a separate data storage layer on the HDFS.

Tajo's system architecture has been designed in such a way to overcome the above shortcomings.

SYSTEM ARCHITECTURE

Figure 1 shows the architecture of Tajo.

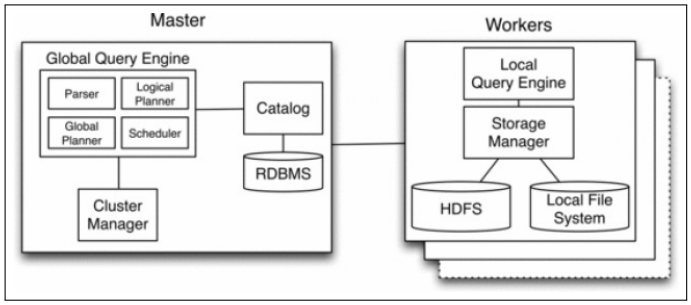

Fig. 1. [1] System Architecture of Tajo

When describing a figure, use reference tag and label to properly locate the figure and don't use the term in this figure. Just explain and refer the figure.
Describe the components like parser, global planner, etc.

[1] A Tajo cluster consists of one master node and a number of workers as shown in the figure. They are connected to one another via high-speed network. Tajo uses HDFS as the storage layer. HDFS consists of one name node (master) and a number of data nodes. A Tajo worker and HDFS data node can run on the same physical machine.

Storage Layer

In [1] they mention that Tajo uses Hadoop Distributed File System (HDFS) as the basic storage layer. The data in HDFS is distributed automatically among the cluster nodes. A local query engine of each worker scans data sets on HDFS. Tajo takes input data from HDFS and later outputs the results back into HDFS. Tajo even has a local file system and its storage manager provides interfaces to the operating system. The physical operators can process data sets on either HDFS or on local file system.

Master

In [1] they also mention that the master is responsible for planning queries and coordinating the activities of workers. The master includes four components, cluster manager, catalog, global query engine, and history manager. All cluster nodes report their resource information like the number of available processors, memory usages, and remaining disk spaces periodically to the cluster manager. The catalog maintains various metadata, such as tables, schemas, partitions, functions, indices, and statistics. Since the metadata are frequently accessed by the global query engine, they are stored in a conventional RDBMS. The global query engine builds a global plan based on the metadata of tables and cluster information which are provided from the catalog and the cluster manager, respectively. Finally, the history manager records the metadata of the executed queries, including query statements, statistics, and logical plans.

Worker

A worker has a query execution engine that performs assigned query. A query unit contains a logical plan and fragments. A fragment is chunk information of an input relation. During execution, a worker sends periodically the reports of the running queries and the resource status to the master which aids in failure.

Grammar

Possible spelling error : cosDmmands
When explaining a figure, try to complete all sections in the figure. Don't need more details, just mention the importance of each component.

QUERY PROCESSING

Tajo has an SQL-like query language, called [8] Tajo Query Language (TQL) which supports most of the SQL coSDmmands. In addition to this, TQL also supports two kinds of variables to indicate a scala value and a temporary table respectively.

Query Planning

Figure 2 shows the steps involved in query transformation.

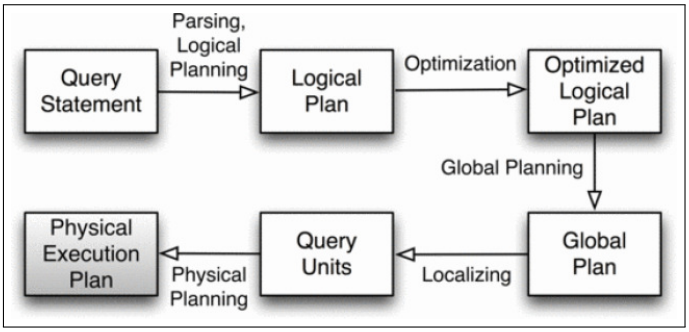

Fig. 2. [1] Query Transformation

In Tajo [1] [4], it has multiple steps to transform a query statement to physical execution plans. When a user submits a query, the global query engine parses the query into an abstract syntax tree and compiles it into a logical plan. The query

optimizer finds the best logical plan which is similar to the original logical plan. This is the optimized logical plan which is transformed into a global query plan. In this step, some logical operators like group-by, sort, and join are transformed into two phase with appropriate repartition methods. Usually, the first phase computes local data on each node, and the intermediate data are range-partitioned or hash-partitioned on the specified keys (e.g., sort keys, grouping keys). The second phase computes the partitioned data on each node. As a result, a global query plan forms of a directed acyclic graph (DAG) of subqueries, which represents a data flow.Based on the physical information of the table, a subquery is localized into a number of query units, each of which is a basic unit of a query executed by a worker. Then, the global query engine schedules the query units along with the DAG of the global plan.

When a worker receives a query unit, it transforms the logical plan of the query unit into a physical execution plan according to its own computing resources (e.g., available memory). As a result, the query units of the same subquery can lead to different physical execution plans on different workers.

Query Execution

In [1] for input and output of data, the authors mention that Tajo has scanners and appenders. A scanner reads input data from HDFS or local file system, whereas an appender writes output data to either of them. In the current implementation, the scanners/appenders of Tajo support CSV and row-based binary file formats. Since a worker executes a DAG of physical operators and Tajo can use various repartition methods, it can do more optimized and efficient query processing.

EXPERIMENT

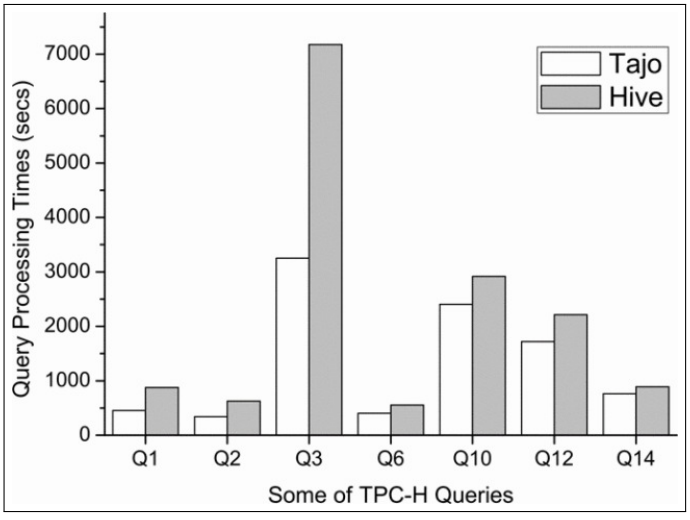

Fig. 3. [1] Performance Evaluation using TPC-H

Don't use in the figure, just describe the components and refer the image. That's enough for a description.

In the [1] paper, the authors have compared the performance of Tajo and Hive by using 1TB TPC-H benchmark set. Figure 3 shows the experimental results. For this experiment, they have used an in-house cluster of 32 nodes, each of which is equipped with 16GB RAM, 4TB HDD, and an Intel i5 quad core CPU. In the figure, the x-axis means the TPC-H queries and the y-axis indicates the processing times. The results show that the time take by Tajo to execute SQL queries is less than Apache Hive on the top of MapReduce.

TAJO SHELL

Tajo provides a shell utility named [8] Tsql. It is a command-line interface where users can create or drop tables, inspect schema and query tables and can execute other sql commands.

For example: bin/tsql [options] [database name]
If a database name is given, tsql connects to the database at startup time else connects to default database.

USE CASES OF TAJO

Data warehousing and analysis

Korea's SK Telecom firm [9] ran Tajo against 1.7 terabytes worth of data and found it could complete queries with greater speed than either Hive or Impala.

Data discovery

The Korean music streaming [9] service Melon uses Tajo for analytical processing. Tajo executes ETL (extract-transform-load process) jobs 1.5 to 10 times faster than Hive.

CONCLUSION

So, with the use of [4] Tajo, efficient data processing and analysis is possible.It processes data faster than the MapReduce Hive framework and provides distributed data warehouse capabilities. By supporting SQL standards and advanced database techniques, Tajo allows direct control of distributed execution and data flow across a variety of query evaluation strategies and optimization opportunities.Lastly, being compatible with ANSI/ISO SQL standard, JDBC driver and various file formats such as CSV, JSON, RCFile etc extends its capabilities further.

ACKNOWLEDGEMENTS

I would like to thank my professor Gregor von Laszewski and all the associate instructors for their constant technical support.
